Ecological Regression with Partial Identification

Wenxin Jiang, Gary King, Allen Schmaltz, Martin A. Tanner

April 23, 2018

Abstract: Ecological inference (EI) is the process of learning about individual behavior from aggregate data. We study a partially identified linear contextual effects model for EI and describe how to estimate the district level parameter averaging over many precincts in the presence of the non-identified parameter of the contextual effect. This may be regarded as a first attempt in this venerable literature to limit the scope of the key form of non-identifiability in EI. To study the operating characteristics of our model, we have amassed the largest collection of data with known ground truth ever applied to evaluate solutions to the EI problem. We collect and study 459 datasets from a variety of fields including public health, political science, and sociology. The datasets contain a total of 2,370,854 geographic units (e.g., precincts), with an average of 5,165 geographic units per dataset. Our replication data are publicly available via the Harvard Dataverse (Jiang et al. 2018) and may serve as a useful resource for future researchers. For all real data sets in our collection that fit our proposed rules, our approach reduces the width of the Duncan and Davis (1953) deterministic bound, on average, by about 45%, while still capturing the true district level parameter in excess of 97% of the time.

Keywords: asymptotics, bounds, confidence intervals, contextual models, ecological inference, linear regression, partial identification.

MSC2010 Classification Codes: 62P25, 62J99
1 Introduction

Ecological Inference (EI) may be described as the problem of making inference on the conditional probability distribution, when only the marginal distributions are known. As an example, voting proportions for Trump $T_i$ are known in each precinct $i$, as well as the proportion of African-Americans $X_i$. However, due to legal reasons, we do not know the proportion of Trump voters among the black voters beyond what is described by a bound by Duncan and Davis (1953). However, under some assumptions, marginal information over many precincts with different proportions of African-Americans may be used to estimate the conditional information, as pointed out by Goodman (1953). Although we will describe EI in terms of the special context of voting behavior with 2x2 tables (such as how black and white citizens vote for Trump or Clinton), King (1997) points out that EI has a wide variety of applications, such as in policy making, epidemiology, marketing, education, and in many similar problems where detailed information needs to be mined from data at an aggregated level. A later book (King, Rosen and Tanner 2004) has collected contributions from 34 authors on many interesting research problems in EI, which testifies to the importance of this research field.

One approach for EI with 2x2 tables is to utilize the model-free bounds of Duncan and Davis (1953). The Duncan and Davis (hereafter, DD) approach has the advantage of not making any assumptions on the data generation process; however, it generally leads to bounds that are relatively wide. On the other hand, regression approaches in EI presented in Goodman (1953) can provide sharp point estimates, which can be very sensitive to the underlying model assumptions. These assumptions will be referred to as the standard EI assumptions. They assume, for example, that white voters in precincts in the United States are equally likely to vote for a particular party’s candidate, regardless of the proportion of black citizens in the precincts in which they live.

In this paper, we consider a method that extends the regression model of Goodman (1953), where, for example, the race specific voting probability can depend linearly on the race proportion of the precinct, with a nonzero slope parameter representing the linear “contextual” effect. This addresses the most important violation of the standard EI assumptions. On the other hand, it is well known (e.g., Owen and Grofman 1997, Chambers and Steel 2001, Wakefield 2004) that modeling dependence of the race specific voting probability on the race proportion by a linear “contextual effect” model can
lead to non-identifiability.

For this unidentifiable linear contextual model, the current paper exploits an observation made in King (1997, Chapter 9). In particular, that work points out that the precinct-level DD bounds themselves carry some information about the contextual effects. It is also clear that there is still a lot of remaining uncertainty about the precise values of these contextual effects. This fits very well in the framework of interval data regression, regressing the precinct-level DD bounds against the race proportion. Although interval data regression can not fully identify the regression coefficients, it can provide identification regions or bounds (see, e.g., Chernozhukov, Hong and Tamer 2007, Liao and Jiang 2010). We will apply this technique in order to bound the unidentified regression parameter that represents the linear contextual effect.

Our bound differs from the model-free bounds such as DD. We have a regression model for the overall behavior and we initially bound the unidentified contextual effect (or the slope parameter). Only after this, will we derive an implied “regression bound” for the district level race specific voting proportion. This implied regression bound can then be intersected with the DD bound to achieve a reduced length.

There are, however, two concerns related to the use of this method. First, the new bound is no longer model-free. It depends on the linear contextual effects assumptions. Violations of the assumptions can cause the resulting intersection bound (i.e., the regression bound intersected with the DD bound) to miss the true district voting proportion, or to even be empty. Second, even if the assumptions hold, the implied regression bound is only derived in the limit of large $p$ (the number of precincts), and it can still miss the true district level voting proportion by an amount on the order of $1/\sqrt{p}$.

To address the second concern, we increase the implied regression bound by a multiple of the standard errors on both sides (similar to forming a confidence interval), before intersecting with the DD bound. To address the first concern, we select only data sets where the implied regression bound has a nonempty intersection with the DD bound. These two ideas combined together turn out to work very well on hundreds of 2x2 datasets constructed from census and other data sources, where the ground truth is known. For most of the selected data sets, the resulting intersection bounds become on average much shorter than the DD bound, yet still contain the true district level proportion.

In summary, the current paper makes three main contributions:
1. We provide bounds for the linear contextual effects in a model that violates the standard assumptions for EI, which previous works have tended to avoid due to issues of non-identifiability.

2. We apply the information obtained on the linear contextual effects to improve the Duncan and Davis (1953) bound, derived more than sixty years ago, for the district level race specific voting proportion.

3. The 459 datasets used to examine the operating characteristics of our model are publicly available via Harvard Dataverse (Jiang et al. 2018) and will serve as a useful resource for researchers in EI, as well as in discrete data model. In this way, we have amassed the largest collection of data with known ground truth ever applied to evaluate solutions to the EI problem.

In the following, we first define the linear contextual model in Section 2 and explain why some of the regression coefficients are not identifiable. We describe how to bound the unidentified regression coefficients in Section 3, and we describe how to bound the the district level voting proportion in Section 4. In Section 5 we introduce confidence intervals for the bounds to account for finite sample variation. In Sections 6 and 7 we provide analytic, simulated, and real data examples. In Section 8 we discuss the generality and limitation of the proposed model. Section 9 provides further discussion. Some technical details are left to the Appendix.

We now describe the linear contextual model and introduce the notation.

2 A linear contextual model

We start with the EI “accounting identity” for precincts $i = 1, ..., p$:

$$T_i = X_i \beta_i^b + (1 - X_i) \beta_i^w. \tag{1}$$

Here, in our running example, $T_i$ is the proportion of voters in precinct $i$ for a candidate of interest, $X_i$ is the proportion of black voters, $\beta_i^b$ is the proportion of voters for a candidate of interest among the black voters, and $\beta_i^w$ is the proportion of voters for a candidate of interest among the non-black voters.

We now allow “contextual effects”, where the race-specific voting behaviors ($\beta_i^b$ and $\beta_i^w$) can possibly be dependent on the “context” (e.g., the black
proportion $X_i$). The following is the only essential assumption that we make in this paper:

**Assumption 1 (Linear contextual effects.)** Assume that $(\beta_i^b, \beta_i^w, X_i)$, for $i = 1, \ldots, p$, are independent and identically distributed (iid) random vectors that satisfy

$$E(\beta_i^w | X_i) = w_0 + w_1 X_i$$

and

$$E(\beta_i^b | X_i) = b_0 + b_1 X_i,$$

where $w_0, w_1, b_0, b_1$ are four non-random real parameters.

Under these assumptions, $(\beta_i^b, \beta_i^w, X_i)$ from each precinct is regarded as a vector of random variables sampled from an underlying probability distribution. The conditional expectations $E(\beta_i^{b,w} | X_i)$ are taken over the conditional distribution of $\beta_i^{b,w}$ given $X_i$, which allows for $\beta_i^{b,w}$ to still be random even after fixing the values of $X_i$. For example, precincts with similar $X_i$'s (e.g., around 0.5) can still have very different race-specific voting proportions, $\beta_i^b$ or $\beta_i^w$.

Under these assumptions, regarding $E(\beta_i^{b,w} | X_i)$, the accounting identity (1) implies that $T_i$ vs $X_i$ satisfies a quadratic regression model:

$$E(T_i | X_i) = w_0 + (b_0 - w_0 + w_1)X_i + (b_1 - w_1)X_i^2.$$  \hspace{1cm} (4)

We will refer to

$$c_1 = b_0 - w_0 + w_1, \quad d_1 = b_1 - w_1,$$  \hspace{1cm} (5)

as the coefficients of $X_i$ and $X_i^2$, respectively. It then follows that

$$E(T_i | X_i) = w_0 + c_1 X_i + d_1 X_i^2.$$  \hspace{1cm} (6)

The three parameters $(w_0, c_1, d_1)$ are identifiable (if the $X_i$’s can take three or more distinct values) and can be estimated by (possibly weighted) least squares regression.

The four regression parameters in the linear contextual effects model are related to the three regression parameters in the quadratic regression of $T_i$ vs $X_i$ via

$$(w_0, w_1, b_0, b_1) = (w_0, w_1, c_1 + w_0 - w_1, d_1 + w_1),$$  \hspace{1cm} (7)

which are partially identifiable up to one free parameter: $(w_0, c_1, d_1)$ are identified, but $w_1$ is not.
Regarding the unknown $w_1$, diverging opinions include setting $w_1 = \max\{-d_1, 0\}$ (Achen and Shiveley 1995; Altman, Gill, and McDonald 2004), $w_1 = 0$ (Wakefield 2004, Section 1.2), or $w_1 = -d_1/2$ (Wakefield 2004, Section 1.2). Our approach differs in an important respect. Instead of picking a value for $w_1$, we will derive a prior-insensitive bound for $w_1$ under the current linear contextual effects model, using the expectations of the Duncan-Davis bounds conditional on the $X_i$’s.\footnote{Although we focus on bounding $w_1$ in this paper, we also could have chosen $b_1 = w_1 + d_1$ as the non-identified parameter instead. The results would be equivalent due to the accounting identity (1). However, in that case a composite parameter $b_0 + b_1$ (instead of simply $w_0$) is identifiable, and the notation would be somewhat clumsier.}

## 3 Bounds on the non-identified $w_1$

### 3.1 Intuition behind the bounding

Denote the Duncan-Davis bounds for the unobserved $\beta_i^w$ as $L_i \leq \beta_i^w \leq U_i$, where $L_i \equiv \max\{0, (T_i - X_i)/(1 - X_i)\}$, $U_i \equiv \min\{1, T_i/(1 - X_i)\}$. Under the linear contextual model $E(\beta_i^w | X_i) = w_0 + w_1 X_i$, the observable Duncan-Davis bounds $L_i \leq \beta_i^w \leq U_i$ form a problem of interval data regression, regressing $[L_i, U_i]$ against $X_i$. It is well known (see, e.g., Chernozhukov, Hong and Tamer 2007, Liao and Jiang 2010) that although interval data regression cannot fully identify the regression coefficients, it can provide their identification regions or bounds. We will use this perspective to derive a bound for the non-identified regression coefficient $w_1$.

Since the Duncan-Davis bounds for $\beta_i^w$ is $L_i \leq \beta_i^w \leq U_i$, the corresponding bound in the conditional expectation is $E(L_i | X_i) \leq E(\beta_i^w | X_i) \leq E(U_i | X_i)$, or

$$E(L_i | X_i) \leq w_0 + w_1 X_i \leq E(U_i | X_i),$$

where $L_i = \min\{0, (T_i - X_i)/(1 - X_i)\}$, $U_i = \min\{1, T_i/(1 - X_i)\}$. The upper and lower bounds are identifiable from observable quantities. Forcing this bound in the entire domain of $X_i$ will lead to a bound for $w_1$.

Consider a very simple example where $T_i \equiv 0.1$ for all $i$. In Figure 1, we illustrate the intuition of how to bound the slope parameter $w_1$ in the linear contextual model $E(\beta_i^w | X_i = x) = w_0 + w_1 x$ for all $x \in (0, 1)$. The intercept parameter is identifiable as $w_0 = E(T_i | X_i = 0) = 0.1$. The slope parameter $w_1$ is non-identified, but only partially so. There are hidden constraints: if
Figure 1: Intuition for bounding $w_1$. The dotted curves are the expectations of the Duncan Davis bounds. The solid lines $0.1 \pm 0.1 x$ are obtained by forcing linear contextual effects $E(\beta^w_i | X_i = x) = w_0 + w_1 x$ to lie between the dotted curves. The dashed lines are examples exceeding the expectation of the Duncan-Davis upper bound (see Section 3.1).
the line \( w_0 + w_1 x = 0.1 + 2x \), then the probability \( E(\beta_i^w | X_i = x) = w_0 + w_1 x \) can exceed 1, so \( w_1 \) cannot be as high as 2 (\( w_1 \leq 2 \)). Even if we choose \( w_0 + w_1 x = 0.1 + 0.9x \) so that \( E(\beta_i^w | X_i = x) = w_0 + w_1 x \) falls between \([0,1]\) for all \( x \in (0,1) \), the line \( 0.1 + 0.9x \) can still exceed a large portion of the dotted curve of the expectation of the Duncan-Davis upper bound \( E(U_i | X_i = x) \). As such, \( w_1 \) also can not exceed 0.9 (\( w_1 \leq 0.9 \)). In fact, to force \( w_0 + w_1 x \) to fall between the dotted curves \([E(L_i | X_i = x), E(U_i | X_i = x)]\) for all \( x \in (0,1) \), we need to have \( w_1 \in [-0.1, 0.1] \), lying in a very narrow interval in this example.

Intuitively, this is how we exploit the expectation of the DD bounds (8) to bound the non-identified contextual effect parameter \( w_1 \). More formally, we have the following theoretical results.

### 3.2 Theory

The following proposition provides a necessary and sufficient condition for this bound in terms of the only non-identified parameter \( w_1 \).

**Proposition 1** Assume a linear contextual effect \( E(\beta_i^w | X_i) = w_0 + w_1 X_i \) for all \( X_i \in A \) where \( A \subset (0,1) \). Then

\[
E(L_i | X_i) \leq E(\beta_i^w | X_i) \leq E(U_i | X_i),
\]

for all \( X_i \in A \), if and only if the non-identified parameter \( w_1 \) satisfies

\[
\sup_{X_i \in A} [(E(L_i | X_i) - w_0) / X_i] \leq w_1 \leq \inf_{X_i \in A} [(E(U_i | X_i) - w_0) / X_i].
\]

Proof: If \( \sup_{X \in A} [(E(L | X) - w_0) / X] \leq w_1 \leq \inf_{X \in A} [(E(U | X) - w_0) / X] \) holds, then for all \( X \in A \), \( [(E(L | X) - w_0) / X] \leq w_1 \leq [(E(U | X) - w_0) / X] \). This implies \( E(L | X) \leq w_0 + w_1 X \leq E(U | X) \) for all \( X \in A \subset (0,1) \).

For the converse: \( E(L | X) \leq w_0 + w_1 X \leq E(U | X) \) for all \( X \in A \subset (0,1) \) implies \( [(E(L | X) - w_0) / X] \leq w_1 \leq [(E(U | X) - w_0) / X] \) holds for all \( X \in A \). Now we take \( \inf_{X \in A} \) for both sides of \( w_1 \leq [(E(U | X) - w_0) / X] \), and take \( \sup_{X \in A} \) for both sides of \( [E(L | X) - w_0) / X] \leq w_1 \). Q.E.D.

The above proposition then gives the tightest bound possible on \( w_1 \). The upper bound and the lower bound are both constructed out of identifiable quantities. The functions \( E(L_i | X_i) \) and \( E(U_i | X_i) \) may be estimated by lowess smoothing. If for some reason we would like to avoid such nonparametric
estimation (e.g., it may not perform well at boundary values of \(X_i\)), we can relax the bounds somewhat and incorporate results from a parametric regression \(E(T_i|X_i) = w_0 + c_1X_i + d_1X_i^2\).

Proposition 2  For all \(X_i \in [l, u] \subset (0,1)\) where \(l < u\), assume linear contextual effect \(E(\beta_i^w|X_i) = w_0 + w_1X_i\) AND a quadratic regression \(E[T_i|X_i] = w_0 + c_1X_i + d_1X_i^2\). Then we have

\[
wl \leq w_1 \leq wu,
\]

where \(wl = \max_{x \in \{l,u\}} \max\{-w_0/x, (w_0 + c_1 + d_1 - 1)/(1-x) - d_1\}\) and \(wu = \min_{x \in \{l,u\}} \min\{(1-w_0)/x, (w_0 + c_1 + d_1)/(1-x) - d_1\}\).

Proof: For the bounds in Proposition 1, note that \(E(U_i|X_i) = E[\min\{1, T_i/(1-X_i)\}|X_i] \leq \min\{1, E[T_i|X_i]/(1-X_i)\}\) due to Jensen’s inequality, and similarly \(E(L_i|X_i) \geq \max\{0, (E[T_i|X_i] - X_i)/(1-X_i)\}\). Now apply a quadratic regression \(E[T_i|X_i] = w_0 + c_1X_i + d_1X_i^2\). Then from Proposition 1 we have

\[
\sup_{X_i \in A} \max\{-w_0/X_i, (w_0 + c_1 - 1 + d_1X_i)/(1-X_i)\}
\]

\[
\leq w_1 \leq \inf_{X_i \in A} \min\{(1-w_0)/X_i, (w_0 + c_1 + d_1X_i)/(1-X_i)\}.
\]

Simplifying these bounds for \(A = [l, u]\) with the boundary points leads to the proof. Q.E.D.

To use Proposition 2, we need to supply the interval \([l, u]\) where we believe the assumptions hold. One could simply use the data range \(l = \min X_i\) and \(u = \max X_i\) of the data set. However, there may be reasons to either reduce this range (e.g., if there are outliers) or increase this range (if there is a belief that the pattern could be reliably extrapolated to some extent beyond the data range). If we attempt to check the assumptions when there is no knowledge regarding the ground truth \(\beta_i^w\), we could still use the \((T_i, X_i)\) data to fit a quadratic curve on \((0,1)\), and superimpose it on the scatterplot, using it to rule out unreasonable choices of a range \([l, u]\). For example, when quadratic regression is based on a scatterplot limited in a small domain of \(X_i \in [0.5, 0.6]\), and extrapolating the fitted quadratic curve to \(x \in [0.1, 0.9]\) leads to \(E(T|X = x) = w_0 + c_1x + d_1x^2\) breaking the “ceiling” of 1 or the “floor” of 0, then it is obvious that the range \([l, u] = [0.1, 0.9]\) is too wide.

On the other hand, the bigger the set \(A = [l, u]\) is for \(X_i\), the tighter the bounds will be in these propositions. Suppose we consider a special case
A → (0, 1). In other words, we assume that the previous quadratic regression model holds for all \( X_i \) in the whole range of (0, 1). Then relaxing the bounds of Proposition 2 and taking \( l \to 0, u \to 1 \), we immediately have:

**Proposition 3** For all \( X_i \in (0, 1) \), assume linear contextual effect \( E(\beta^w_i | X_i) = w_0 + w_1 X_i \) AND a quadratic regression \( E[T_i | X_i] = w_0 + c_1 X_i + d_1 X_i^2 \). Then we have

\[
wl \leq w_1 \leq wu,
\]

where \( wl = \max\{-w_0, c_1 + w_0 - 1\} \) and \( wu = \min\{1 - w_0, c_1 + w_0\} \).

The above are the bounds for the non-identified contextual effect parameter \( w_1 \). In practice, we are interested in predicting the district level race-specific vote. In the next section, bounds for such quantities are derived from any bound on \( w_1 \).

4 Applying the \( w_1 \)-bound to bound the district level parameter

4.1 Estimating the district level parameter \( B \) by a point estimate \( B(\lambda, w_1, \theta) \) given \( w_1, \lambda, \) and \( \theta \).

We first analyze the precinct level parameter \( \beta^b_i \). Denote residuals as \( e^b_i = \beta^b_i - E(\beta^b_i | X_i) \), \( e^w_i = \beta^w_i - E(\beta^w_i | X_i) \), and \( e^T_i = T_i - E(T_i | X_i) = e^b_i X_i + e^w_i (1 - X_i) \). Note that for any real \( \lambda \) possibly dependent on \( i \),

\[
\beta^b_i = E(\beta^b_i | X_i) + \lambda(T_i - E(T_i | X_i)) + e^b_i - \lambda e^T_i
\]

\[= w_0 + (c_1 - w_1) + (w_1 + d_1) X_i + \lambda(T_i - w_0 - c_1 X_i - d_1 X_i^2) + e^b_i - \lambda e^T_i
\]

\[= [w_0 + c_1 + d_1 X_i] + \lambda(T_i - w_0 - c_1 X_i - d_1 X_i^2) + w_1 (X_i - 1) + (e^b_i - \lambda e^T_i)
\]

\[\equiv b_i(\lambda, w_1, \theta) + (e^b_i - \lambda e^T_i).
\]

(9)

Here \( \theta \equiv (w_0, c_1, d_1)^T \).

The district level parameter is given as

\[
B \equiv \sum_{i=1}^{p} N_i X_i \beta^b_i / \sum_{i=1}^{p} N_i X_i
\]

(10)
\[
\frac{\sum_{i=1}^{p} N_i X_i b_i(\lambda, w_1, \theta)}{\sum_{i=1}^{p} N_i X_i} + \frac{\sum_{i=1}^{p} N_i X_i (e_i^b - \lambda e_i^T)}{\sum_{i=1}^{p} N_i X_i}.
\]

Here, \(N_i\) denotes the size of the \(i\)th precinct, which will be incorporated as another random variable in the \(iid\) framework, in order to allow the precincts to have different sizes. It is possible to extend our work to include additional covariates and treat \(N_i\) (or its suitable transformation) as a covariate. Here, we simply modify our assumption on the linear contextual effects so that (2) and (3) hold conditional on both \(X_i\) and \(N_i\) on the entire support of these random variables.

Due to the Law of Large Numbers, for large \(p\), we can ignore the second term of the expansion of (10) with the mean zero residuals \((e_i^b - \lambda e_i^T)\), when estimating \(B\). We can then form a point estimate of \(B\) using the first term:

\[
B(\lambda, w_1, \theta) \equiv \frac{\sum_{i=1}^{p} N_i X_i b_i(\lambda, w_1, \theta)}{\sum_{i=1}^{p} N_i X_i} - \frac{w_1 \sum_{i=1}^{p} N_i X_i (1 - X_i)}{\sum_{i=1}^{p} N_i X_i},
\]

where

\[
b_i(\lambda, w_1, \theta) \equiv [w_0 + c_1 + d_1 X_i] + \lambda(T_i - w_0 - c_1 X_i - d_1 X_i^2) + w_1(X_i - 1).
\]

### 4.2 The district level point estimate \(B(\lambda, w_1, \theta)\) is insensitive to \(\lambda\) and sensitive to \(w_1\).

Note that

\[
B(\lambda, w_1, \theta) - B(0, w_1, \theta) = \frac{\sum_{i=1}^{p} N_i X_i \lambda e_i^T}{\sum_{i=1}^{p} N_i X_i}.
\]

This is an average of mean-0 residuals, which will be approximately 0 due to the Law of Large Numbers. Therefore we know that \(B(\lambda, w_1, \theta)\) varies little with \(\lambda\) for large \(p\).

Different choices of \(\lambda\) will therefore make very little difference for large values of \(p\). The choice of \(\lambda\) may still influence the district level parameter at the order of \(O_p(1/\sqrt{p})\). A possible approach to optimizing \(\lambda\) at this finer level will be discussed in Remark 3, but it will be mainly left as possible future work. In this paper, we choose \(\lambda = 1\) for illustration.
In contrast to its insensitive dependence on $\lambda$, the point estimate $B(\lambda, w_1, \theta)$ will vary greatly with $w_1$ due to (11), at a level that does NOT disappear for large $p$. The sensitivity on $w_1$ can be measured by

$$\frac{\partial B(\lambda, w_1, \theta)}{\partial w_1} = -r \equiv -\frac{\sum_{i=1}^p N_i X_i (1 - X_i)}{\sum_{i=1}^p N_i X_i},$$

(13)

which is typically nonzero (unless $X_i \in \{0, 1\}$ for all nonempty precincts). This term quantifying the sensitivity on $w_1$ does not converge to 0 even for large $p$. Therefore the bounds we derived earlier for $w_1$ will be very useful here for limiting the scope of the influence by $w_1$.

Now for any possible value of the partially identified $w_1$, the district level parameter $B = \sum_i N_i X_i \beta_{ib} / \sum_i N_i X_i$ is estimated by the point estimator $B(\lambda, w_1, \theta)$ following (11). We will now use the bounds on $w_1$ to bound this district level parameter estimate $B(\lambda, w_1, \theta)$, and estimate its $\theta$ parameter by regression.

### 4.3 Bounding the district level point estimate $B(\lambda, w_1, \theta)$ by $[\hat{B}l, \hat{B}u]$, for unknown $w_1$, with $\theta$ estimated by $\hat{\theta}$.

Due to Propositions 2 or 3, we know that $w_1 \in [w_l, w_u]$, where $wu = wu(\theta)$ and $wl = wl(\theta)$ depend on $\theta$. Then

$$B(\lambda, w_1, \theta) \in [Bl, Bu] \equiv [B(\lambda, wu(\theta), \theta), B(\lambda, wl(\theta), \theta)].$$

(14)

The parameters $\theta = (w_0, c_1, d_1)^T$ can be estimated from a least squares regression

$$\hat{\theta} = (\hat{w}_0, \hat{c}_1, \hat{d}_1)^T \leftarrow \min_{w_0,c_1,d_1} \sum_{i=1}^p \rho_i [T_i - (w_0 + c_1 X_i + d_1 X_i^2)]^2,$$

(15)

possibly weighted by some weight $\rho_i$.

Replacing $\theta$ in (14) by $\hat{\theta}$, we obtain the estimated bounds for the district parameter $B$. Since this is implied from a regression model of linear contextual effects, one may call this a “regression bound”. In summary, this will be our proposed interval estimate for $B$:

**Definition 1 (Regression Bound.)** A Regression Bound for the district parameter $B = \sum_i N_i X_i \beta_{ib} / \sum_i N_i X_i$ is of the form

$$[\hat{B}l, \hat{B}u] \equiv [B(\lambda, wu(\hat{\theta}), \hat{\theta}), B(\lambda, wl(\hat{\theta}), \hat{\theta})],$$

(16)
where the functional form of the point estimate $B(\lambda, w_1, \theta)$ follows (11), $wu = wu(\theta)$ and $wl = wl(\theta)$ are the bounds of the $w_1$ parameter according to Proposition 2 or Proposition 3, and $\hat{\theta}$ estimates the regression coefficients $\theta$ from (15).

5 Asymptotic conservative confidence intervals for $B$

The previous regression bound $[\hat{B}l, \hat{B}u]$ for $B$ does not take into account sampling variation. It assumes, for example, that the quadratic regression coefficients $\hat{w}_0, \hat{c}_1, \hat{d}_1$ are the true coefficients, while in reality they are estimated from $p$ precincts and are subject to sampling error. Due to sampling error, it may be possible that according to the sample estimates, $B \notin [B_l, B_u]$, even if the model assumptions for linear contextual effects are valid, when we should automatically have $B \in [\hat{B}l, \hat{B}u]$ in the large $p$ limit. (See Appendix B.) To solve this problem, we will provide asymptotic conservative confidence intervals for $B$ in this section, where $\hat{B}l$ will be reduced (and $\hat{B}u$ will be increased) by a typical size of the sampling variation.

Since $[\hat{B}l, \hat{B}u] \equiv [B(\lambda, wu(\hat{\theta}), \hat{\theta}), B(\lambda, wl(\hat{\theta}), \hat{\theta})]$ depends on the functional forms of $wl(\cdot)$ and $wu(\cdot)$, we first need to analyze in detail these functional forms.

In Propositions 2 and 3, the bounds $wl$ and $wu$ are functions of the quadratic regression coefficients $\theta = (w_0, c_1, d_1)^T$. The lower bounds can be expressed in the form
\[
wl(\theta) = \max_{j=1}^{J} \{ gl_j^0 + gl_j^T \theta \},
\]
and the upper bounds can be expressed in the form
\[
wu(\theta) = \min_{j=1}^{J} \{ gu_j^0 + gu_j^T \theta \}.
\]

For Propositions 2, $J = 4$, $gl_1^0 = 0$, $gl_1^T = (-1/l, 0, 0)$, $gl_2^0 = -1/(1 - l)$, $gl_2^T = (1/(1 - l), 1/(1 - l), 1/(1 - l) - 1)$,
\[ gl^0_0 = 0, \quad gl^0_1 = (1 - 1/u, 0, 0), \quad gl^0_2 = -1/(1 - u), \quad gl^0_4 = (1/(1 - u), 1/(1 - u), 1/(1 - u) - 1), \]
\[ gu^0_0 = 1/l, \quad gu^0_1 = (-1/l, 0, 0), \quad gu^0_2 = 0, \quad gu^0_2 = gl^T_2, \]
\[ gu^0_3 = 1/u, \quad gu^T_3 = (-1/u, 0, 0), \quad gu^T_4 = 0, \quad gu^T_4 = gl^T_4. \]

For Proposition 3, \( J = 2, \)
\[ gl^0_0 = 0, \quad gl^0_1 = (1, 0, 0), \quad gl^0_2 = -1, \quad gl^T_2 = (1, 1, 0), \]
\[ gu^0_0 = 1, \quad gu^T_1 = (-1, 0, 0), \quad gu^0_2 = 0, \quad gu^0_2 = (1, 1, 0). \]

Using this notation, we have the following result:

**Proposition 4** Let \( B = \frac{\sum_{i=1}^{p} N_i X_i \beta_i}{\sum_{i=1}^{p} N_i X_i} \) be the district parameter of voting proportion for a candidate of interest among all the black people in a district with \( p \) precincts. Let \( DD \) be the Duncan and Davis (1953) bound for \( B \), following

\[
DD = \left[ \frac{\sum_{i=1}^{p} N_i \max\{0, T_i - (1 - X_i)\}}{\sum_{i=1}^{p} N_i X_i}, \frac{\sum_{i=1}^{p} N_i \min\{T_i, X_i\}}{\sum_{i=1}^{p} N_i X_i} \right].
\] (19)

For any choice of \( \lambda \in [0, 1] \), as \( p \to \infty \), an asymptotic conservative confidence interval for \( B \) of the form:

\[
CI_x = [\hat{BL} - xSL, \hat{BU} + xSU] \cap DD,
\] (20)

has asymptotic coverage probability at least \( \Phi(x) \).

Here we use the following system of notation:
\[ x > 0, \]
\[ \hat{\theta^T} = (\hat{\omega}, \hat{e}_1, \hat{d}_1) \] which is estimated by quadratic regression (15), which has robust sandwich asymptotic variance matrix \( V \),
\[ \lambda \in [0, 1], \]
\[ r \equiv \sum_i N_i X_i (1 - X_i), \]
\[ h_0 \equiv \sum_i N_i X_i \lambda T_i, \]
\[ h^T \equiv \sum_i N_i X_i (1 - \lambda, 1 - \lambda X_i, X_i - \lambda X_i^2), \]
\[ S_1 = \sqrt{\sum_i \left( \frac{N_i X_i (1 + \lambda)/2 - \lambda X_i)}{\sum_i N_i X_i} \right)^2}, \]
\[ \hat{BL} = \max_j \{\hat{BL}_j\}, \]

\[ \text{See, e.g., https://www.stata.com/manuals/p_robust.pdf} \]
\( \hat{BU} = \min_{j=1}^{J} \{ \hat{BU}_j \} \).

For \( j = 1, \ldots, J \), the \( \hat{BL}_j \)'s and \( \hat{BU}_j \)'s are defined after (17) and (18),
\[
\hat{BL}_j = h_0 - rg_{u_0}^j + (h - rg_{u_0})^T \hat{\theta},
\]
\[
\hat{BU}_j = h_0 - rgl_{0}^j + (h - rgl_{0})^T \hat{\theta},
\]
\[
SL_j \equiv S_1 + \sqrt{\tau} V (h - rg_{u_0}^j),
\]
\[
SU_j \equiv S_1 + \sqrt{\tau} V (h - rgl_{0}^j),
\]
\[
SL = SL_{\hat{j}} \text{ where } \hat{j} \equiv \arg \max_{j=1}^{J} \{ \hat{BL}_j \},
\]
\[
SU = SU_{\tilde{j}} \text{ where } \tilde{j} \equiv \arg \min_{j=1}^{J} \{ \hat{BU}_j \}.
\]

For this result to hold, we assume that the linear contextual model holds conditional on both \( N_i \) and \( X_i \) on the entire support of these random variables, and also for all \( X_i \) in a range specified in either Proposition 2 or Proposition 3. We assume that the robust variance \( V \) is of order \( O_p(1/p) \). In addition, we assume the following “tie-breaking” conditions:

(i) Assume that \( N_i X_i (1 - X_i) \) is not almost surely 0.

(ii) Assume that the minimizing entry of \( w_u = \min_{j=1}^{J} \{ gu_0^j + gu_j^T \theta \} \) is unique and not tied with the other entries, and similarly the maximizing entry of \( w_l = \max_{j=1}^{J} \{ gl_0^j + gl_j^T \theta \} \) is unique and not tied with the other entries.

(iii) Assume that \( w_u(\theta) \neq w_l(\theta) \).

A derivation of this confidence interval \( CI_x \) in Proposition 4 is included in Appendix A.

**Remark 1** The tie breaking conditions can be checked by examining the data at hand. The condition on \( N_i \) and \( X_i \) is satisfied if \( N_i \) is not almost surely 0 and if \( X_i \) does not almost surely take a boundary value (0 or 1) for nonempty precincts with \( N_i > 0 \). The conditions on \( \theta \) will hold for almost all true parameters (except on a set with Lebesgue measure 0, where some of the \( 2J \) points \( \{ gu_0^j + gu_j^T \theta, gl_0^j + gl_j^T \theta, j = 1, \ldots, J \} \) are exactly tied). In the Bayesian sense when \( \theta \) is regarded as a vector of continuous random variables, these conditions hold with probability one, since any ties would force \( \theta \) to lie on a lower dimensional manifold which has zero Lebesgue measure.

**Remark 2** Instead of the analytic method described here, one may consider using the bootstrap to estimate the standard deviation (std) of the bound estimate \( \hat{BL} \) (and similarly for \( \hat{BU} \)), and replace the \( SL \) in the formula of \( CI_x \)
by $sd_{boot}(\hat{BL})$. However, we suspect that this bootstrap method would not be theoretically valid here. The reason is that we are not interested in how much $\hat{BL}$ varies from its own non-stochastic large sample limit, i.e., the typical size of $\hat{BL} - \lim_{p \to \infty} \hat{BL}$. We are really interested in the typical size of $\hat{BL} - B$ instead. However, the district level parameter $B = \sum_{i=1}^{p} \frac{N_i X_i \beta_i^b}{\sum_{i=1}^{p} N_i X_i}$ is a non-identified stochastic quantity, and its sampling variations would be ignored by bootstrapping $\hat{BL}$ alone. Nevertheless, in practice, the bootstrap method may still work well heuristically for describing the sampling variation.

**Remark 3** The proposed confidence interval $[\max_j \{\hat{BL}_j\} - xSL, \min_j \{\hat{BU}_j\} + xSU]$ has width $\min_j \{\hat{BU}_j\} - \max_j \{\hat{BL}_j\} + x(SL+SU)$, where only $S = SU + SL$ depends on $\lambda$. It is possible to define the best $\lambda \in [0,1]$ by minimizing $S$, but we will leave this for future work.

In the numerical examples below, we currently simply choose $\lambda = 1$ for illustration.

### 6 Analytic and Simulated Examples

We will compare the proposed bound $CI_x$ to the Duncan and Davis (1953) bound $DD$, as defined in Proposition 4. For any interval $A$, we will use $|A|$ to denote its length. We will use $x = 0$ and $x = 1$ for illustration.

To measure the success of the proposed method, we examine:

1. whether the new interval estimate contains the true district parameter: $B \in CI_x$.

2. how narrow the new interval estimate is compared to the DD bound: the width ratio $WR_x \equiv |CI_x|/|DD|$.

In the examples below, we assume $X \sim Unif[0,1]$, and $N_i$ is constant for all $i$, unless otherwise stated.

**Example 1:** $\beta^b_i = T + \tau (1 - X_i) \in [0,1]$, and $\beta^w_i = T - \tau X_i \in [0,1]$, where probability constraints entail $\tau \in \pm \min(T, 1 - T)$ and $T \in (0,1)$. Then the plot $T_i$ against $X_i$ is a flat $T_i = T$. Here one can show by Proposition 3 that $[wl, wu] = \pm \min(T, 1 - T)$. In this case, in the limit of large precincts and large number of precincts (large $N_i$ and
Example 2: $\beta^b_i = \tau(1 - X_i)$, $\beta^w_i = 1 - \tau X_i$, where $\tau \in [0, 1]$. Then the plot $T_i$ against $X_i$ is $T_i = (1 - X_i)^2$. Here one can show by Proposition 3 that $[wl, wu] = [-1, -1]$, so $w_1$ is identified. In this case, in the limit of large precincts and large number of precincts (large $N_i$ and $p$), it can be shown analytically that $B \approx E\beta^b_i = \tau/3 \in CI_0 \approx [0, 1/3], DD \approx [0, 1/2]$. Also, $WR_0 \equiv |CI_0|/|DD| \approx 1/3$. In summary, the proposed bound tightens the DD bound while still containing the true parameter.

Example 3: $\beta^b_i = 0$, $\beta^w_i = 1 - X_i$. Then the plot $T_i$ against $X_i$ is $T_i = (1 - X_i)^2$. Here one can show by Proposition 3 that $[wl, wu] = [-1, 0]$, so $w_1$ is identified. In this case, in the limit of large precincts and large number of precincts (large $N_i$ and $p$), it can be shown analytically that $B \approx E\beta^b_i = \tau/3 \in CI_0 \approx [0, 1/3], DD \approx [0, 1/2]$. Also, $WR_0 \equiv |CI_0|/|DD| \approx 2/3$. In summary, the proposed bound tightens the DD bound while still containing the true parameter.

Example 4: Consider $p = 1000$ precincts all with population $N_i = 150$. We generate $p = 1000$ precincts all with population $N_i = 150$ for this example. For sample estimates based on this finite data set, we obtain true $B = 0$, $DD = [0, 0.301843]$.

We apply Proposition 2 for this example with $[l, u] = [\min(X_i), \max(X_i)] = [0.001473298, 0.9988792]$. We obtain $\hat{Bl} = 2.269362e-05$ and $\hat{Bu} = 0.0003054308$ which are very close to $B = 0$, but $CI_0 = [\hat{Bl}, \hat{Bu}]$ excludes the true $B$ due to sampling variation. On the other hand, the proposed interval estimate narrowly misses the true $B$ due to sampling variation. The confidence interval $CI_x$ for $x = 1$ is $[-0.01146876, 0.01181847] \cap DD = [0, 0.01181847]$, which does contain the true $B$ now and is still very narrow. (Here, intersection with the Duncan Davis bound improves the lower bound to be 0.) In summary, the regression bound $CI_0$ can miss the true parameter due to sampling variation. However, after expanding the bound to account for the sampling variation, $CI_1$ does contain the true parameter $B$ and is still much narrower than the DD bound.

Example 4: Consider $p = 1000$ precincts all with population $N_i = 150$. We
let $X_i \sim Unif[0, 0.95]$, $\beta_i^b \approx (N_i X_i)^{-1} Bin(N_i X_i, 1/(1 + \exp(-b0 - b1 * X_i - (1-X_i)\epsilon_i^b)))$, $\beta_i^w \approx (N_i (1-X_i))^{-1} Bin(N_i (1-X_i), 1/(1+\exp(-w0 - w1 * X_i - (1-X_i)\epsilon_i^w)))$ (the approximation here involves operations such as rounding $N_i X_i$ and adding 1 to avoid zero or fractional counts), where $\epsilon_i^{b,w}$s are iid $N(0, s^2)$, $s = 0.5$, $b0 = 2.197225$, $b1 = -1.791759$, $w0 = 2.197225$, $w1 = 0$, $T_i \approx \beta_i^b X_i + \beta_i^w (1 - X_i)$ (the approximation here involves operations such as replacing $X_i$ by a rounded version of $N_i X_i$ divided by $N_i$). The resulting $T_i$ vs $X_i$ scatterplot is given by Figure 2.

Figure 2: $T$ vs $X$ scatterplot for Example 4.
We apply Proposition 2 for this example with \([l, u] = [\min(X_i), \max(X_i)] = [0.001399633, 0.9489353]\).

In this case it can be shown that \(B = 0.7335825 \in CI_0 = [0.7044503, 0.7509661] \subset DD = [0.6362682, 0.9316473]\). Also, \(WR_0 \equiv |CI_0|/|DD| = 0.1574785\).

The \(CI_1\) is \([0.6895103, 0.7659441]\), which is also narrower than the DD interval and contains the true \(B\).

Example 5: Consider \(p = 1000\) precincts all with population \(N_i = 150\). We let \(X_i \sim Unif[0, 0.7]\), \(\beta^b_i \approx (N_iX_i)^{-1}Bin(N_iX_i, 1/(1 + \exp(-b0 - b1 \times X_i - (1 - X_i) \epsilon^b_i)), \beta^w_i \approx (N_i(1-X_i))^{-1}Bin(N_i(1-X_i), 1/(1+\exp(-w0-w1 \times X_i - (1 - X_i) \epsilon^w_i))\) (the approximation \(\approx\) here involves operations such as rounding \(N_iX_i\) and adding 1 to avoid zero or fractional counts), where \(\epsilon^b,w_i\)'s are iid \(N(0, s^2)\), \(s = 1\), \(b0 = 0\), \(b1 = 0\), \(w0 = 2.197225\), \(w1 = 0\), \(T_i \approx \beta^b_i X_i + \beta^w_i(1 - X_i)\) (the approximation \(\approx\) here involves operations such as replacing \(X_i\) by a rounded version of \(N_iX_i\) divided by \(N_i\)). The resulting \(T_i\) vs \(X_i\) scatterplot is given by Figure 3.

We apply Proposition 2 for this example with \([l, u] = [\min(X_i), \max(X_i)] = [0.001031308, 0.6992155]\).

In this case it can be shown that \(B = 0.4993419 \in CI_0 = [0.3998952, 0.759834] \subset DD = [0.3403412, 0.9613881]\). Also, \(WR_0 \equiv |CI_0|/|DD| = 0.579568\).

The \(CI_1\) is \([0.3711763, 0.7978435]\), which is also narrower than the DD interval and contains the true \(B\).

The \(CI_1\) used in Examples 3, 4, and 5 will have at least \(\Phi(1) \approx 84\%\) coverage probability asymptotically, according to Proposition 4. In repetitions of 1000 simulations, we found that \(CI_1\) is very conservative: \(P[B \in CI_1] = 934/1000, 1000/1000, 1000/1000\), respectively, in Examples 3, 4, and 5. The mean width of \(CI_1\) divided by the mean width of the DD bound is \(0.2912078, 0.2753775, 0.6999836\), respectively. These results demonstrate that the proposed confidence intervals are considerably more informative about \(B\) compared to the DD bounds, as shown in repeated simulations.

It is noted that in Examples 4 and 5, the true models do not follow the linear contextual model or quadratic regression of \(T_i\) vs \(X_i\). The \(\beta^w,b_i\)'s follow overdispersed logistic regression model with heteroscedastic normal random effects.
Figure 3: T vs X scatterplot for Example 5.
7 Real data analyses

Given that information is inherently lost in the observable information in datasets used for EI, it is important to develop models for the task on datasets with distributions similar to those used for inference. Unfortunately, for the very reason that EI is utilized in the first place, datasets with true labels in target application areas, such as elections and voting rights litigation, are typically not available for legal reasons. The nature of the learning problem is thus intrinsically different than a traditional supervised learning problem. As such, most recent work on EI has evaluated approaches using a relatively small set of datasets with ground truth on other social variables, such as voter registration and literacy, combined with artificial, simulated data (e.g., Wakefield 2004; Imai et al. 2008). Here, we significantly increase the number of datasets with ground truth labels on social data for evaluation of our proposed model, as well as to serve as a testbed for future approaches to the $2 \times 2$ case.

7.1 Data

We construct a new set of datasets for developing and evaluating EI approaches from datasets used in previous work for EI and new datasets constructed from publicly available data. Datasets from previous work (e.g., King 1997; Wakefield 2004; Imai et al. 2008) include data on voter registration and race in 1968; literacy by race in 1910; and party registration in south-east North Carolina in 2001$^3$. We also collect data from the Centers for Disease Control and Prevention on mortality rates by gender and race (CDC 2017); literacy rates and educational attendance by gender from the 2001 Census of India (Office of the Registrar General & Census Commissioner 2001); and additional datasets from the US Census and American Community Surveys from 1850 to 2016 via the Integrated Public Use Microdata Series (Ruggles et al. 2017). In total, we collected 459 datasets. The datasets contain a total of 2,370,854 geographic units (e.g., precincts), with an average of 5,165 geographic units per dataset and a median of 478, ranging from 145 to a maximum of 41,783. Our replication data are publicly available via Harvard Dataverse (Jiang et al. 2018).

$^3$In the latter case, we subset the data to create $2 \times 2$ tables.
7.2 Analysis

Our approach aims to still produce scientifically appropriate statements (including “we don’t know anything”) even in the presence of (a) violations of assumptions and (b) cases where too much of the information in the individual level was aggregated away. Two simple heuristics are used: (I) We only consider the bounds, \( CI_x \), valid if \( \hat{Bl} \leq \hat{Bu} \) and \( DD \) covers part of \( CI_0 \); and (II) we may impose an additional restriction to only consider data with \( \lvert DD \rvert < 0.7 \). Heuristic (I) eliminates cases when the bounds flip, which can occur in practice when assumptions are violated. (This is equivalent to applying the proposed bounds only to data sets with nonempty \( CI_0 \). A theoretic support for this heuristic can be found in Appendix B, Remark 5.) Heuristic (II) eliminates cases in which the amount of information lost in aggregation is relatively high. Importantly, these heuristics can be applied when the ground truth is unknown, so they can be applied at inference time in real applications.

We observe that the proposed bounds consistently capture the true value more often than the nominal coverage intervals. Table 1 displays effectiveness on all of the datasets for differing levels of confidence, \( \Phi(x) \), when heuristic (I) alone is applied.\(^4\) About 63 percent of the datasets (289 out of 459) are retained after applying heuristic (I). As the confidence level increases, there is a tradeoff to be made between the capture probability of the district-level \( B \) and the width-ratio. The capture probabilities can be further improved by using both heuristics (I) and (II), see Table 2. About 39 percent of the datasets (181 out of 459) are retained after applying both aforementioned heuristics. Compared with Table 1, \( p(B \in CI_x | \text{selected}) \) is increased and \( E[WR_x | \text{selected}] \) is decreased when both heuristics (1) and (2) are used. In both tables, we notice that as the confidence level increases, there is a tradeoff to be made between the capture probability of the district-level \( B \) and the width-ratio. In practice, with \( x = 0.5 \), which we consider a reasonable tradeoff between the capture probability and the width-ratio for the observed datasets, only 4 out of the 181 retained datasets are such that \( B \notin CI_x \), when both heuristics (I) and (II) are applied. The average width ratio for these 181 data sets is about 55%, demonstrating the improvement of the proposed bound over the DD bound.

The parameter of 0.7 of Heuristic (II) was chosen on a held-out, random split of the data. Increasing the value increases the proportion selected at

\(^4\)As noted above, we use \( \lambda = 1 \) in the empirical experiments.
the expense of the capture probability, and decreasing the value decreases the proportion selected to the point where datasets that are well-modeled by the approach are not selected (i.e., the problem cases tend to be those in which the DD bounds are wide). Other possible heuristics are the subject of future work, as noted in Section 8.

| \( x \) | \( \Phi(x) \) | \( p(B \in CI_x|\text{selected}) \) | \( E[WR_x|\text{selected}] \) |
|---|---|---|---|
| 0.00 | 0.5000 | 0.8374 | 0.4338 |
| 0.25 | 0.5987 | 0.8927 | 0.5261 |
| 0.50 | 0.6915 | 0.9377 | 0.5977 |
| 0.75 | 0.7734 | 0.9585 | 0.6562 |
| 1.00 | 0.8413 | 0.9619 | 0.7056 |
| 1.25 | 0.8944 | 0.9654 | 0.7474 |
| 1.50 | 0.9332 | 0.9758 | 0.7856 |
| 1.75 | 0.9599 | 0.9896 | 0.8193 |
| 2.00 | 0.9772 | 0.9965 | 0.8497 |

Table 1: Effectiveness in terms of the nominal coverage probability, \( \Phi(x) \); proportion of intervals that capture the true district value among those selected, \( p(B \in CI_x|\text{selected}) \); and the width ratio of among those selected, \( E[WR_x|\text{selected}] \). In this case, 62.96 percent of the datasets are selected by heuristic (I).

8 Generality and limitation of the current work

Our work makes a single pair of essential assumptions (2) and (3) on the linear contextual effects. This is more general than the traditional methods which assume zero contextual effects, which are often falsified by real data with knowledge of the ground truth.

When assumptions (2) and (3) fail, it can be shown that our method does not always work. The key question in practice is how can one know about such violations. Unfortunately, it is theoretically possible that such violations can not be detected by data without knowledge of the ground truth. Consider the following example:
Table 2: Effectiveness in terms of the nominal coverage probability, $\Phi(x)$; proportion of intervals that capture the true district value among those selected, $p(B \in CI_x|\text{selected})$; and the width ratio of among those selected, $E[WR_x|\text{selected}]$. In this case, 39.43 percent of the datasets are selected by heuristics (I) and (II).

| $x$  | $\Phi(x)$ | $p(B \in CI_x|\text{selected})$ | $E[WR_x|\text{selected}]$ |
|------|------------|---------------------------------|---------------------------|
| 0.00 | 0.5000     | 0.8564                          | 0.3652                    |
| 0.25 | 0.5987     | 0.9227                          | 0.4718                    |

| 2.00 | 0.9772     | 1.0000                          | 0.8261                    |

Example 6: Suppose $X_i \sim Unif[0, 1]$ and $N_i$ is independent of $X_i$ and $\beta_{b,w}^i$. Suppose we have quadratic contextual effects $\beta_b^i = T + b_2 (X_i^2 - 1), \beta_w^i = T + b_2 (X_i^2 + X_i)$, where to ensure these are probabilities valued in $[0, 1]$ for all possible $X$, we restrict $T \in (0, 1)$ and $b_2 \in \{\max\{-T/2, -(1 - T)\}, \min\{T, (1 - T)/2\}\}$. Then $T_i = \beta_b^i X_i + \beta_w^i (1 - X_i) = T$. The observed data $(X_i, T_i)$ would be the same as our Example 1 earlier ($T_i = T$). We have already found that the large sample limit of our proposed bound is $CI_0 = T \pm (1/3) \min\{T, 1 - T\}$. The large sample limit of true $B$ is now $E(N_i X_i \beta_b^i)/E(N_i X_i) = T - b_2/2$. It is then possible that for large enough $b_2$, $B \notin CI_0$ (e.g., when $b_2 = T = 1/3$). The same holds in the large sample limit for $CI_x$ with any $x > 0$, since the sampling variation that differentiates between $CI_x$ and $CI_0$ disappears in the large sample limit.

If all datasets were generated from this model (e.g., with $b_2 = T = 1/3$), then the asymptotic coverage probability of any $CI_x$ would be 0 and we would not be able to avoid such data sets without the knowledge of the ground truth. Fortunately, this kind of “non-detectable violation” happens quite rarely. For example, the non-detectable violation in Example 6 is caused by the quadratic effects in $\beta_b^i$ and $\beta_w^i$ canceling each other exactly by chance.
In addition, our interval estimates are robust in the sense that even a small amount of violation of the assumptions would not matter. For example, the quadratic effect $b_2$ does not have to be exactly 0 for $CI_0$ to capture $B$. This is in contrast to traditional point estimates and their confidence intervals, which will miss the true parameter due to any bias when the sample size $p$ is sufficiently large, since the width of the confidence interval typically shrinks at the rate of $1/\sqrt{p}$.

From hundreds of real data sets on which we evaluated the approach, we found that most practically important violations can be easily detected if $CI_0$ is empty (i.e., the regression bound either flips, or does not intersect with the DD bound at all). Appendix B examines this analytically for the limit of large $p$ (see Remark 5). The logic there is to prove that if the assumptions hold, then $CI_0$ should not be empty. Therefore if $CI_0$ is found to be empty, then something must be wrong about the assumptions.

As shown in Section 7, we tried hundreds of real data sets (with knowledge of the ground truth), and in most cases, we have nonempty $CI_0$. When applying the $CI_x$ for $x > 0$ on the selected data sets with nonempty $CI_0$, we found that our conservative confidence interval $CI_x$ tends to capture the true district parameter $B$ more often than the stated level of confidence $\Phi(x)$, while tightening the DD bound. For example, $CI_{0.5}$ has nominal coverage probability about 70%, but it actually captures $B$ more than 90% of the selected data sets.\footnote{As Section 7 indicates, the actual percentage of captures may be further improved with an additional restriction on studying data sets with $|DD| < 0.7$.} For the selected data sets where $CI_{0.5}$ misses $B$, most of them are data sets in which the $X_i$'s represent the gender proportion in a particular precinct. Gender data are known to be problematic for EI. Their $X_i$'s tend to focus on a short range near 0.5, with possibly influential outliers near 0 or 1.

In addition to data with a short range of $X$, data with influential observations may also cause the proposed method to fail (either by not selecting the data via the heuristics, or by selecting the data and missing the true district level value) when data points $(X_i, T_i)$ seem to belong to several different clusters. In these situations, we found that a divide and conquer strategy may be helpful. One could divide the data into several parts and apply either the proposed bound or the DD bound to each part, depending on the observed pattern in the particular part. The proposed bound could be applied to any part of the data that displays a common pattern (e.g., those of
linear or quadratic regression). For parts of the data that are outliers or that otherwise lack a clear pattern for linear or quadratic regression, one could apply the DD bound. The bounds would then be combined by weighting the number of people in each part of the data to obtain a single bound. In initial experiments of such an approach, we segmented the data visually and found that this strategy can sometimes rectify the misses or nonselection of the current method. We leave automating the process of segmentation to future work.

9 Discussion

An alternative approach is to assume nonlinear contextual effects such as $E(\beta^b_i|X_i) = 1/(1+e^{-b_0-b_1X_i})$ and $E(\beta^w_i|X_i) = 1/(1+e^{-w_0-w_1X_i})$. At first sight this seems to avoid the non-identifiability problem in the model $E(T_i|X_i) = X_i/(1 + e^{-b_0-b_1X_i}) + (1 - X_i)/(1 + e^{-w_0-w_1X_i})$. However, the limitations of such an approach are noted by Wakefield (2004, Section 1.3):

Unfortunately, assuming nonlinearity theoretically removes the nonidentifiability but in practice is totally dependent on the form chosen, and parameter estimates will in general be highly unstable. This was pointed out by Achen and Shively (1995: 117), who comment that since the contextual effects are not strong and the range of $X$ is often not $(0, 1)$, it would be virtually impossible to discriminate between nonlinear and linear forms (since any function that has a narrow range and does not change greatly may be well approximated with a linear form, via a Taylor series expansion).

In contrast, our current work directly confronts the non-identifiability problem by modeling the linear contextual effects and generates interesting insights on the bounds of the unidentified parameter and on the sensitivity of its effect, which can not be easily derived in the nonlinear model where unstableness of the point estimates is hidden in a nontrivial way.

Our model has derived how the district level parameter depends on the non-identified parameter on linear contextual effect. There is only one such non-identified parameter, which could allow sensitivity analysis, such as based on (13).
The current work only considers the black proportion $X_i$ for the contextual effect. One may consider adding other covariates to the contextual effect models for modeling $\beta_i^b$ and $\beta_i^w$. The current paper only focuses on inference regarding the district level parameter. It would be interesting to obtain a useful bound for the precinct level parameters $\beta_i^b$, probably by modeling the distribution of the residuals $(\beta_i^b - E(\beta_i^b | X_i), (\beta_i^w, E(\beta_i^w | X_i))$, or at least the second moments such as $\text{var}((\beta_i^b, \beta_i^w)^T | X_i)$. (The residuals average out in the district level estimates, so we could still get useful bounds for the district level parameter in the current paper, even without modeling the residuals.) Also, it would be interesting to extend the idea of this paper to the case of more general RxC tables, for which Cho and Manski (2008) have derived model-free bounds that generalize those of Duncan and Davis (1953).

Appendix A: A derivation of the confidence interval $CI_x$ in Proposition 4 and some comments

Note that from (9), $\beta^b_i = b_i(\lambda, w, \theta) + (e_i^b - \lambda e_i^T)$, where the residual $(e_i^b - \lambda e_i^T)$ has mean 0.

For the district level parameter, the residuals can be averaged out over many precincts due to the central limit theorem and we can get a potentially useful conservative confidence interval, without modeling the variance of the residuals:

$$B = \frac{\sum_i N_i X_i \beta^b_i}{\sum_i N_i X_i} = \frac{\sum_i N_i X_i [b_i(\lambda, w, \theta) + (e_i^b - \lambda e_i^T)]}{\sum_i N_i X_i}$$

$$B = \frac{\sum_i N_i X_i (e_i^b - \lambda e_i^T)}{\sum_i N_i X_i} + \frac{\sum_i N_i X_i b_i(\lambda, 0, \theta)}{\sum_i N_i X_i} - w_1 \frac{\sum_i N_i X_i (1 - X_i)}{\sum_i N_i X_i}.$$  

The unidentified parameter $w_1 \in [wl, wu]$.

Therefore $B \in [BL(\theta), BU(\theta)]$, where

$$BL(\theta) = \frac{\sum_i N_i X_i (e_i^b - \lambda e_i^T)}{\sum_i N_i X_i} + \frac{\sum_i N_i X_i b_i(\lambda, 0, \theta)}{\sum_i N_i X_i} - w_u(\theta) \frac{\sum_i N_i X_i (1 - X_i)}{\sum_i N_i X_i};$$

$$BU(\theta) = \frac{\sum_i N_i X_i (e_i^b - \lambda e_i^T)}{\sum_i N_i X_i} + \frac{\sum_i N_i X_i b_i(\lambda, 0, \theta)}{\sum_i N_i X_i} - w_l(\theta) \frac{\sum_i N_i X_i (1 - X_i)}{\sum_i N_i X_i}.$$  

Here $wl, wu$ depend linearly on $\theta \equiv (w_0, c_1, d_1)$. The $b_i(\lambda, 0, \theta) \equiv b_i^0 + (b_i^1)^T \theta \equiv \lambda T_i + (1 - \lambda, 1 - \lambda X_i, X_i - \lambda X_i^2)(w_0, c_1, d_1)^T$ also depends linearly
on \( \theta \equiv (w_0, c_1, d_1) \), which is estimated by quadratic regression (15) as \( \hat{\theta} \equiv (\hat{w}_0, \hat{c}_1, \hat{d}_1) \), with robust asymptotic variance matrix \( V = \hat{\text{avar}}(\hat{\theta}) \) based on a sandwich formula.\(^6\)

Denote the first term in \( BL(\theta) \) or \( BU(\theta) \) as

\[
\text{TERM}_1 = \sum_i N_i X_i (e_i^b - \lambda e_i^T) / \sum_i N_i X_i.
\]

Then \( E(\text{TERM}_1) = 0 \). Assuming independent precincts, then the first term \( \text{TERM}_1 \) has asymptotic variance \( \text{Var}(\text{TERM}_1) = \sum_i \left( \frac{N_i X_i}{\sum_i N_i X_i} \right)^2 \text{var}(e_i^b - \lambda e_i^T | N_i, X_i). \) Note that \( \text{var}(e_i^b - \lambda e_i^T | N_i, X_i) = \text{var}(\beta_i^b - \lambda T_i | N_i, X_i) = \text{var}((1 - \lambda X_i) \beta_i^b - \lambda (1 - X_i) \beta_i^w | N_i, X_i) \equiv \text{var}(\epsilon_i | N_i, X_i) \), where \( \beta_i^b \) and \( \beta_i^w \) are probabilities valued in \([0, 1]\). Then \( \epsilon \equiv (1 - \lambda X_i) \beta_i^b - \lambda (1 - X_i) \beta_i^w \) has a range \([-\lambda (1-X_i), 1-\lambda X_i]\), if we restrict \( \lambda \in [0, 1/X_i] \). The variance of a bounded random variable in \([a, b]\) is at most \([|b-a|/2]^2 \). Therefore, \( \text{var}(\epsilon_i | N_i, X_i) \leq [(1 + \lambda)/2 - \lambda X_i]^2 \) and \( \text{Var}(\text{TERM}_1) \leq \sum_i \left( \frac{N_i X_i [(1+\lambda)/2 - \lambda X_i]}{\sum_i N_i X_i} \right)^2 \). Therefore, we know that the asymptotic standard error of the first term is bounded above by

\[
\text{sd}(\text{TERM}_1) \leq S_1 = \sqrt{\sum_{i=1}^p \left( \frac{N_i X_i [(1+\lambda)/2 - \lambda X_i]}{\sum_i N_i X_i} \right)^2},
\]

if we choose \( \lambda \in [0, 1] \) (which guarantees \( \lambda \in [0, 1/X_i] \) for all \( i \)).

Now \( w \equiv w_l(\theta) \) is of the form \( \max_{j=1}^l \{ g_{lj}^0 + g_{lj}^T \theta \} \) for some constant vectors \( g_{lj} \); \( uu \equiv uu(\theta) \) is of the form \( \min_{j=1}^l \{ g_{uj}^0 + g_{uj}^T \theta \} \), for some constant vectors \( g_{uj} \). Denote \( r \equiv \sum_i N_i X_i (b_i^0 - (b_i^1)^T \theta) / \sum_i N_i X_i \), \( h_0 \equiv \sum_i N_i X_i b_i^0 / \sum_i N_i X_i \), \( h \equiv \sum_i N_i X_i b_i^1 / \sum_i N_i X_i \).

Then

\[
BL(\theta) = \text{TERM}_1 + \sum_i N_i X_i (b_i^0 + (b_i^1)^T \theta) / \sum_i N_i X_i - \min_{j=1}^l \{ g_{uj}^0 + g_{uj}^T \theta \} r
\]

\[= \text{TERM}_1 + h_0 + h^T \theta - \min_{j=1}^l \{ g_{uj}^0 + g_{uj}^T \theta \} r.
\]

We can write \( BL(\theta) = \max_{j=1}^l \{ BL_j \} \) where \( BL_j = \text{TERM}_1 + h_0 - r g_{uj}^0 + (h - r g_{uj})^T \theta \). Similarly, we can write \( BU(\theta) = \min_{j=1}^l \{ BU_j \} \) where \( BU_j = \text{TERM}_1 + h_0 - r g_{uj}^0 + (h - r g_{lj})^T \theta \).

Now define
\[ \hat{BL} = \max_{j=1}^{J} \{ \hat{BL}_j \}, \tag{21} \]
where \( \hat{BL}_j = h_0 - rgu_j^0 + (h - rgu_j)^T \hat{\theta}; \)
\[ \hat{BU} = \min_{j=1}^{J} \{ \hat{BU}_j \}, \]
where \( \hat{BU}_j = h_0 - rgl_j^0 + (h - rgl_j)^T \hat{\theta}. \)

[It can be verified that in the previous notation of (16), we have \( \hat{BL} = B(\lambda, wu(\hat{\theta}), \hat{\theta}) \) and \( \hat{BU} = B(\lambda, wu(\hat{\theta}), \hat{\theta}). \]

Note that
\[ \hat{BL}_j - BL_j = -TERM_1 + (h - rgu_j)^T (\hat{\theta} - \theta); \]
\[ \hat{BU}_j - BU_j = -TERM_1 + (h - rgl_j)^T (\hat{\theta} - \theta). \]

By an asymptotic normality argument, \( \hat{BL}_j \approx N(BL_j, sl_j^2) \) where \( sl_j \leq \sum_{i} N_i X_i (1 - X_i) \) is a positive number due to the law of large numbers. Assume that \( wu(\theta) \neq wu(\hat{\theta}) \) (and therefore \( BU(\theta) \neq BL(\theta) \)). Then \( wu \) can be close (within \( O_p(1/\sqrt{p}) \)) to only one of the end points of \( [wu(\theta), wu(\hat{\theta})] \), and consequently \( B \) can be close to only one end point of \( [BL(\theta), BU(\theta)] \). Without loss of generality we assume that \( B \) is close to \( BL(\theta). \) (The other possibility would be similar.) Assume that the minimizing entry of \( wu = \min_{j=1}^{J} \{ gu^0_j + gu_j^0 \theta \} \) is unique and not tied with the other entries. Then the maximizing entry \( BL(\theta) = \max_{j=1}^{J} \{ BL_j \} \) is unique and has an order-1 gap from the other entries, that is greater than \( O_p(1/\sqrt{p}) \), which is the order of all \( (BU_j - BU_j) \)'s and \( (BL_j - BL_j) \)'s. Therefore \( \max_{j=1}^{J} \{ \hat{BL}_j \} \) (= \( \hat{BL} \)) and \( \max_{j=1}^{J} \{ BL_j \} \) (= \( BL(\theta) \)) are achieved at a same \( j \), with probability tending to 1 as \( p \to \infty \). We will call this same \( j \) as \( \hat{j} \). Then
\[ \hat{BL} = \hat{BL}_j = BL_j + (\hat{BL}_j - BL_j) \]
\[ = BL(\theta) + (\hat{BL}_j - BL_j) \]

where the last term is asymptotically normal and of order \( O_p(1/\sqrt{p}) \).

There is a similar equation relating \( \hat{BU} \) to \( BU(\theta) \). These imply that the \( \hat{BU} \) is close to \( BU(\theta) \).

Since we have assumed that \( B \) is only close to one end point \( BL(\theta) \), and not close to \( BU(\theta) \), then \( B \) must not be close to \( \hat{BU} \) or \( \hat{BU} + u' \) either, for any \( u' \) of order \( O_p(1/\sqrt{p}) \). Then we have \( P(B > \hat{BU} + u') \) converges to 0. Then \( P(B \notin [\hat{BL} - l', \hat{BU} + u']) \approx P(B < BL - l') \approx P(B < BL(\theta) - l' + (\hat{BL}_j - BL_j)) \leq P(l' < (\hat{BL}_j - BL_j)) \) since \( B > BL(\theta) \).

Then \( P(l' < (\hat{BL}_j - BL_j)) \approx \Phi(-l'/sl_j) \leq \Phi(-l'/SL_j) = \Phi(-x) \) if we take \( l' = xSL \). Setting \( u' = xSU \) of order \( O_p(1/\sqrt{p}) \) leads to an approximate upper bound of \( P(B \notin [\hat{BL} - l', \hat{BU} + u']) \) being \( 1 - \Phi(-x) = \Phi(x) \) (for large \( p \)). Q.E.D.

**Remark 4** The coverage probability of \( CI_x \) can be improved to 1, if we have \( w_1 \) lying in the interior of the bound \((w_l, w_u)\). This would allow any \( x > 0 \) to be used in finding a confidence interval. However, the condition on \( w_1 \) cannot be checked due to its non-identifiability. The tie-breaking conditions that we assumed about the identified \( \theta \), however, can be checked by data. Then we can, e.g., use \( x = 1 \) and achieve coverage probability at least \( \Phi(x) \approx 84\% \), or use \( x = 1.282 \) and achieve at least 90\% coverage probability.
Appendix B: Non-emptiness of $CI_0$ when the assumptions hold and the sample size is large enough

In this Appendix B, we prove in the large $p$ limit that when model assumptions hold, $CI_0$ should be nonempty.

By tracing the definition of $CI_0$ and applying the Law of Large Numbers, we find that in the large sample limit

$$CI_0 = \left[ \inf_{v_1 \in [wl_j, wu_j]} B(\lambda, v_1, \theta), \sup_{v_1 \in [wl_j, wu_j]} B(\lambda, v_1, \theta) \right] \cap DD,$$

where $DD$ denotes the large sample limit of the DD bound,

$$B(\lambda, v_1, \theta) = E\{N_i X_i[(w_0 + c_1 + d_1 X_i) + v_1 (X_i - 1)]\}/E\{N_i X_i\}$$

as summarized in (11) and (12) before, and $[wl_j, wu_j]$, $j \in \{1, 2, 3\}$ indicate the bound of $w_1$ to be used according to the $j$th Proposition.

**Proposition 5** (Non-emptiness of $CI_0$.) For $j \in \{1, 2, 3\}$, assume linear contextual effects $E(\beta^w_i | X_i, N_i) = w_0 + w_1 X_i$ and $E(\beta^w_i | X_i, N_i) = b_0 + b_1 X_i$, and let $[wl_j, wu_j]$ indicate the bound of $w_1$ to be used according to the $j$th Proposition. Define in the large sample limit

$$CI_0 = \left[ \inf_{v_1 \in [wl_j, wu_j]} B(\lambda, v_1, \theta), \sup_{v_1 \in [wl_j, wu_j]} B(\lambda, v_1, \theta) \right] \cap DD,$$

where

$$DD = \left[ E[N_i \max\{0, T_i - (1 - X_i)\}] / E\{N_i X_i\}, E[N_i \min\{T_i, X_i\}] / E\{N_i X_i\} \right],$$

and

$$B(\lambda, v_1, \theta) = E\{N_i X_i[(w_0 + c_1 + d_1 X_i) + v_1 (X_i - 1)]\}/E\{N_i X_i\},$$

where $c_1, d_1$ follow (5).

Then $CI_0$ is nonempty.

Proof:

$$B(\lambda, v_1, \theta) = E\{N_i X_i[(w_0 + c_1 + d_1 X_i) + v_1 (X_i - 1)]\}/E\{N_i X_i\}$$
\[ E\{N_i X_i [(w_0 + c_1 X_i + d_1 X_i^2 - (w_0 + v_1 X_i)(1 - X_i)]/X_i} \}
\]
\[ = E\{N_i X_i [(T_i - (w_0 + v_1 X_i)(1 - X_i)]/X_i} \}
\]
\[ = E\{N_i X_i [\beta^b_i X_i + \beta^w_i (1 - X_i) - (w_0 + v_1 X_i)(1 - X_i)]/X_i} \}
\]
\[ = E\{N_i X_i [\beta^b_i X_i + (w_0 + w_1 X_i)(1 - X_i) - (w_0 + v_1 X_i)(1 - X_i)]/X_i} \}
\]
\[ = E\{N_i X_i [\beta^b_i + (w_1 - v_1)(1 - X_i)]/X_i} \]
\[ \equiv B + (w_1 - v_1)r. \]

where we denote \( r = E\{N_i X_i (1 - X_i)]/E\{N_i X_i \} \) and \( B = E\{N_i X_i \beta^b_i \}/E\{N_i X_i \}. \) Then
\[ CI_0 = [B + (w_1 - w u_j)r, B + (w_1 - w l_j)r] \cap DD. \]

On the other hand, the \( j \)th Proposition implies that
\[ w_1 \in [w l_j, w u_j]. \]

Then
\[ B \in [B + (w_1 - w u_j)r, B + (w_1 - w l_j)r], \]

since \( r \geq 0. \) Now we also have
\[ B \in DD, \]

since
\[ X_i \beta^b_i = T_i - (1 - X_i) \beta^w_i \in [\max\{0, T_i - (1 - X_i)\}, \min\{T_i, X_i\}] \]
due to Duncan and Davis (1953). Then we have
\[ B \in [B + (w_1 - w u_j)r, B + (w_1 - w l_j)r] \cap DD = CI_0 \]
in the large sample limit. Therefore \( CI_0 \) is non-empty.

Q.E.D.

**Remark 5** In practice, one can apply the converse of this Proposition to rule out data sets with empty \( CI_0 \), which likely suggests either some assumptions are violated or the size of the data is not large enough for the method to work reliably. The logic is that the interval should not be empty if the assumptions all hold and the sample size is large enough.
